AN APPROACH TO DISCRETE OPERATOR LEARNING BASED ON SPARSE HIGH-DIMENSIONAL APPROXIMATION*

DANIEL POTTS† AND FABIAN TAUBERT†

Abstract. We present a dimension-incremental method for function approximation in bounded orthonormal product bases to learn the solutions of various differential equations. Therefore, we decompose the source function of the differential equation using parameters like Fourier or spline coefficients and treat the solution of the differential equation as a high-dimensional function with respect to the spatial variables, to these parameters, and also to further possible parameters from the differential equation itself. Finally, we learn this function in the sense of sparse approximation in a suitable function space by detecting coefficients of the basis expansion with the largest absolute values. Investigating the corresponding indices of the basis coefficients yields further insights into the structure of the solution as well as its dependency on the parameters and their interactions. This allows a reasonable generalization to even higher dimensions and therefore better resolutions of the decomposed source function.

Key words. sparse approximation, nonlinear approximation, high-dimensional approximation, dimension-incremental algorithm, partial differential equations, operator learning

1. Introduction. In mathematical analysis, partial differential equations (PDEs) stand as formidable tools when it comes to modeling diverse phenomena across various scientific disciplines from fluid dynamics to quantum mechanics. Unfortunately, solving PDEs analytically as well as numerically can be quite difficult and thus becomes a challenging task. The numerical solution of PDEs is investigated thoroughly already since the mid-20th century until today by various well-known methods like finite difference methods [30], spectral methods [6, 37], or finite element methods (FEMs) [40]. On the other hand, with the advance in artificial intelligence (AI), several new methods using machine learning techniques are currently arising and are investigated for finding solutions of PDEs, including physics-informed neural networks (PINNs) [12, 26, 34, 35], convolutional neural networks [14], deep operator networks [8, 13, 32], multilevel Picard approximations [9, 19], and neural operators [20, 27, 29, 31, 33], among numerous others.

It is not necessary to emphasize that both the classic and the AI methods have various advantages and disadvantages, which are being increasingly studied in the last few years [3, 16]. Especially for high-dimensional PDEs and for many-query settings, where multiple solutions of the PDE with respect to varying parameters, initial or boundary conditions are needed, machine learning algorithms have proven to outperform classical methods significantly. One of the main reasons for this is the great performance of neural networks in the framework of operator learning on PDEs, i.e., learning the underlying solution operator of a PDE that maps initial and/or boundary conditions as well as other parameters of the PDE to the solution. For a comprehensive overview of operator learning theories, algorithms, and applications, we refer the readers to the recent surveys [5, 28].

However, with respect to operator learning of simpler differential equations, classical methods can still compete with machine learning. As an example, consider the one-dimensional

differential equation

$$\mathcal{L}u = f,$$

with the differential operator $\mathcal{L} = \frac{d}{dx}$ and initial condition u(0) = 0. Assume the right-hand side function f to be given (or at least be well approximated) by a partial Fourier sum

$$f(x) = \sum_{\ell=0}^{N-1} f_{\ell} e^{2\pi i \ell x}.$$

If we denote the vector of Fourier coefficients $\mathbf{f} = (f_0, \dots, f_{N-1}) \in \mathbb{C}^N$, we now aim for a solution u of the form

(1.2)
$$u(x, \mathbf{f}) = \sum_{\mathbf{k} \in I} u_{\mathbf{k}} T_{\mathbf{k}}(x, \mathbf{f}),$$

with unknown coefficients $u_k \in \mathbb{C}$ and an unknown and sparse index set $I \subset \mathbb{N}^{N+1}$, where

$$T_{\boldsymbol{k}}(\boldsymbol{z}) \coloneqq \prod_{j=1}^d T_{k_j}(z_j), \quad \text{with} \quad T_{k_j}(z_j) = \begin{cases} 1 & k_j = 0, \\ \sqrt{2}\cos(k_j\arccos(z_j)) & k_j \neq 0, \end{cases}$$

are multivariate Chebyshev polynomials of dimension d=N+1. Note that sparsity is a crucial requirement here since a high-dimensional approximation of such form for non-sparse index sets I is almost always computationally unfeasible due to the curse of dimensionality. On the other hand, sparsity occurs naturally, based on the way we discretize the function f, as we show below. The behavior that the solution is dominated by main effects and some low-order interactions will reappear in our numerical experiments as a result of our general approach. A similar effect is known as the sparsity-of-effects principle in other fields of analysis; cf. [17, 38].

Due to the simple structure of \mathcal{L} and the initial condition, we know that

$$u(x, \mathbf{f}) = f_0 x + \sum_{\ell=1}^{N-1} \frac{f_\ell}{2\pi \mathrm{i} \ell} \mathrm{e}^{2\pi \mathrm{i} \ell x},$$

which can be rewritten using the univariate Chebyshev polynomials $T_0(z)=1$ and $T_1(z)=\sqrt{2}z$ as

$$u(x, \mathbf{f}) = \frac{1}{2} T_1(x) T_1(f_0) \prod_{j=1}^{N-1} T_0(f_j) + \sum_{\ell=1}^{N-1} e^{2\pi i \ell x} \frac{T_1(f_\ell)}{2\sqrt{2}\pi i \ell} \prod_{\substack{j=0\\j \neq \ell}}^{N-1} T_0(f_j)$$

since all the f_{ℓ} appear only linearly and decoupled. From this formula, we can directly find the structure of the index set I as

$$I = \left\{ \begin{bmatrix} 1\\1\\0\\0\\\vdots\\0 \end{bmatrix}, \begin{bmatrix} 0\\0\\1\\\vdots\\0 \end{bmatrix}, \dots, \begin{bmatrix} 0\\0\\0\\1\\\vdots\\0 \end{bmatrix}, \begin{bmatrix} 1\\0\\0\\1\\\vdots\\0 \end{bmatrix}, \dots, \begin{bmatrix} 1\\0\\0\\1\\\vdots\\0 \end{bmatrix}, \begin{bmatrix} 2\\0\\0\\1\\\vdots\\0 \end{bmatrix}, \dots, \begin{bmatrix} 2\\0\\0\\1\\\vdots\\0 \end{bmatrix}, \dots \right\},$$

with the first row corresponding to the spatial dimension x and the remaining rows corresponding to the coefficient dimensions f_0, \ldots, f_9 , following the order.

Therefore, we in fact know the index set I, and it can be used to compute the corresponding basis coefficients u_k simply by using, e.g., Chebyshev rank-1 lattices [22]. So if the structure of a suitable index set I in (1.2) can be computed exactly, then the hardest part of the approximation problem is already done, and it allows us to use high-dimensional cubature methods like Monte Carlo (MC) or Quasi-Monte Carlo (QMC) methods to derive the coefficients u_k . A similar approach in the Fourier setting for a more complicated differential equation was investigated in [15] and showed great results, even for very high dimensions. Further, the parameterization of the right-hand side function f as well as the representation of the solution f by its basis coefficients f is closely related to the concept of so-called encoder and decoder mappings, as for example used in [18]. There, the existence of reasonable neural and spectral operators wrapped by such encoder and decoder mappings as well as their error bounds were studied. The fundamental difference of our approach is the missing decoder since we use the Fourier coefficients f as the encoding of the function f directly to compute the solution f via (1.2).

Unfortunately, a direct analysis of the structure of the a priori unknown index set I is often extremely difficult or simply impossible due to the complexity of the considered differential problem. Thus, instead we use a dimension-incremental algorithm presented in [24], using point samples to detect a suitable index set I adaptively. More precisely, our general aim is to solve the high-dimensional approximation problem of approximating (1.2) by detecting a reasonable and sparse index set I containing the indices k corresponding to the largest (in absolute value) coefficients u_k . Thus, we are using samples $u(x^{(j)}, f^{(j)})$ of the solution u, which we obtain by solving the differential equation (1.1) for the fixed parameters $f^{(j)}$. The adaptive detection of a good index set I is made possible by the usage of adaptively chosen sampling points $(x^{(j)}, f^{(j)})$, and hence adaptive training data in the algorithm, which is one of the biggest differences of this approach compared with several deep learning techniques for operator learning associated with PDEs, where random training data are assumed.

The dimension-incremental algorithm in [24], based on the method from [25], works in arbitrary bounded orthonormal product bases (BOPB) and is capable of computing proper approximations with satisfying error bounds based on the underlying cubature method, as shown for the Fourier case in [2]. To generate the necessary point samples of the solution u, we will utilize classical differential equation solvers like the FEM. Once we detect the index set I, we can analyze its structure to gain insight into the interactions between the different parameters and variables and also on their influence on the solution u. Further, we can generalize the structure of the index set I to proceed to even higher-dimensional or more detailed versions of the differential problem with a reasonable a priori guess, whose coefficients u_k will be important therein.

This leads to an efficient and interpretable approximation of the solution u, expressed similarly as in (1.2), allowing direct evaluations of u for any right-hand side f that is either of the same form or can be well approximated by it—without repeatedly solving the PDE. This operator-based perspective on PDE solvers offers an appealing alternative to classical model-based approaches, in which the structure of the differential operator is explicitly exploited to construct efficient solution algorithms. Our method can be seen as a synthesis of model-based and data-driven approaches: although we rely on sample-based recovery, the use of a structured index set and the decomposition into interpretable basis functions connect our framework closely to analytical PDE solvers, where solution structures are derived symbolically or semi-analytically. As such, it provides both interpretability and generalizability, thereby addressing one of the major limitations of many purely machine learning-based methods. In contrast to

neural operator approaches or physics-informed neural networks (PINNs), which often operate as black-box models with limited insight into the underlying solution structures, our method maintains a clear connection to the analytical properties of the PDE and offers explicit control over the approximation process through the choice of a basis and index sets.

The remainder of this paper is organized as follows: In Section 2, we properly introduce our notations and the theoretical framework for the application of the dimension-incremental algorithm from [24], which is also briefly explained there. Section 3 then investigates several test examples to present the application of our method. These examples include the Poisson and heat equations, where we have their analytical solutions at hand to compare with our results, and several more advanced differential problems like parametric diffusion equations with random coefficients and the nonlinear Burgers' equation. Finally, we give a brief conclusion in Section 4.

A Python code is available at https://github.com/fabiantaubert/nabopb. It contains the dimension-incremental algorithm, the necessary rank-1 lattice cubature methods, and the differential equation applications.

2. Theory.

2.1. Setting. We investigate differential equations of the general form

$$\mathcal{L}u = f,$$

with a differential operator $\mathcal{L}:\mathcal{U}\to\mathcal{F}$, a right-hand side $f\in\mathcal{F}$, and the corresponding solution $u\in\mathcal{U}$. Here, \mathcal{U} and \mathcal{F} are suitable function spaces defined on the Lipschitz smooth d-dimensional spatial domain $\Omega\subset\mathbb{R}^d$. A typical example for the spaces \mathcal{U} and \mathcal{F} , which will also appear in our numerical experiments in Section 3, are the Sobolev space $H^1(\Omega)$ and its dual $H^{-1}(\Omega)$. Furthermore, together with boundary conditions like Dirichlet or Neumann conditions, the solution u can be defined even on the closure Ω .

To ensure that the differential problem (2.1) is well-posed, we require certain conditions for the existence and uniqueness of the solution. A problem is said to be well-posed if there is a solution, the solution is unique, and the solution depends continuously on the data. These conditions are typically guaranteed through appropriate assumptions on the operator \mathcal{L} , the function spaces \mathcal{U} and \mathcal{F} , and the boundary conditions.

For example, in the case where $\mathcal{U}=H^1(\Omega)$ and $\mathcal{F}=H^{-1}(\Omega)$, the Lax-Milgram theorem can be applied for elliptic problems to guarantee the existence and uniqueness of the solution under suitable conditions on the bilinear form associated with \mathcal{L} . In other cases, the Fredholm alternative or other functional analysis results may be used to establish these properties. Additionally, the regularity of the solution often depends on the smoothness of the data and the boundary conditions, which in turn influences the choice of suitable function spaces for the approximation.

2.2. Sparse approximation. Assuming that (2.1) has a unique solution for each right-hand side function $f \in \mathcal{F}$, our goal is to learn the solution mapping $\mathcal{G} : \mathcal{F} \to \mathcal{U}$, ending up with an approximation $\tilde{\mathcal{G}}$ of \mathcal{G} .

In order to do, so we start by approximating the function f by

(2.2)
$$f(\boldsymbol{x}) \approx \sum_{j=1}^{n} a_{j} A_{j}(\boldsymbol{x}), \quad \boldsymbol{x} \in \Omega,$$

with some fixed functions $A_j, j = 1, ..., n$, and coefficients $\mathbf{a} = (a_1, ..., a_n) \in \mathbb{C}^n$. Favorable approximative parameterizations of the function f by the coefficients \mathbf{a} should be

accurate and efficient, i.e., the possible error should be reasonably bounded, and there exist fast methods to compute the coefficients a for a given function f and vice versa.

Further, we assume that the solution $u: \mathcal{D} \to \mathbb{C}$ has a basis expansion of the form

(2.3)
$$u(\boldsymbol{x}, \boldsymbol{a}) \coloneqq \sum_{\boldsymbol{k} \in \mathbb{N}^{d+n}} c_{\boldsymbol{k}} \Phi_{\boldsymbol{k}}(\boldsymbol{x}, \boldsymbol{a}), \qquad (\boldsymbol{x}, \boldsymbol{a}) \in \mathcal{D},$$

with $\{\Phi_{\pmb{k}}: \pmb{k} \in \mathbb{N}^{d+n}\}$ a bounded orthonormal product basis (BOPB) in the separable Hilbert space $\mathcal{H} = L_2(\mathcal{D}, \mu)$ on the Cartesian product-type domain \mathcal{D} and the basis coefficients $c_{\pmb{k}} \in \mathbb{C}, \pmb{k} \in \mathbb{N}^{d+n}$. See [24, Sec. 1.1] for more details on the notion of a BOPB and the corresponding domains and spaces. Further, see Remark 2.1 for the relation between the domains \mathcal{D} and $\overline{\Omega} \times C^n$, which would be the canonical domain for u since $\pmb{x} \in \overline{\Omega}$ and $\pmb{a} \in \mathbb{C}^n$. Having (2.3), we aim to approximate u by a truncated series

$$S_I u(\boldsymbol{x}, \boldsymbol{a}) \coloneqq \sum_{\boldsymbol{k} \in I} c_{\boldsymbol{k}} \Phi_{\boldsymbol{k}}(\boldsymbol{x}, \boldsymbol{a}),$$

with some a priori unknown index set $I \subset \mathbb{N}^{d+n}$, $|I| < \infty$, followed by an approximation

(2.4)
$$S_I^{\mathcal{A}} u(\boldsymbol{x}, \boldsymbol{a}) \coloneqq \sum_{\boldsymbol{k} \in I} \hat{u}_{\boldsymbol{k}} \Phi_{\boldsymbol{k}}(\boldsymbol{x}, \boldsymbol{a}),$$

where $\hat{u}_{k} \in \mathbb{C}$, $k \in I$, are approximations of the true coefficients c_{k} . Note that the detection of a "good" index set I in general leads to a nonlinear approximation problem. With (2.4) we then have an approximation of the solution mapping: For every right-hand side f, we determine the coefficients a and plug them into $S_{I}^{\mathcal{A}}u$, which yields us an explicit representation of an approximation of u. So in fact, combining the discretization mapping $f \mapsto a$ with the approximation mapping $a \mapsto S_{I}^{\mathcal{A}}u(\cdot,a)$ yields an approximation \tilde{G} of the solution map $G: \mathcal{F} \to \mathcal{U}$. Furthermore, the structure of the index set I as well as the size of the corresponding approximated coefficients \hat{u}_{k} may reveal interesting insights into the structure of the solution u and its dependence on the coefficients a, i.e., on the right-hand side function f.

Estimating the error of the approximation in the L_{∞} -norm and using the bound of our basis functions Φ_{k} , we get

$$\begin{aligned} \left\| u - S_{I}^{\mathcal{A}} u \right\|_{\infty} &\leq \left\| u - S_{I} u \right\|_{\infty} + \left\| S_{I} u - S_{I}^{\mathcal{A}} u \right\|_{\infty} \\ &= \left\| \sum_{\mathbf{k} \notin I} c_{\mathbf{k}} \Phi_{\mathbf{k}} \right\|_{\infty} + \left\| \sum_{\mathbf{k} \in I} (c_{\mathbf{k}} - \hat{u}_{\mathbf{k}}) \Phi_{\mathbf{k}} \right\|_{\infty} \\ &\leq \sum_{\mathbf{k} \notin I} |c_{\mathbf{k}}| \left\| \Phi_{\mathbf{k}} \right\|_{\infty} + \sum_{\mathbf{k} \in I} |c_{\mathbf{k}} - \hat{u}_{\mathbf{k}}| \left\| \Phi_{\mathbf{k}} \right\|_{\infty} \\ &\leq B \left(\sum_{\mathbf{k} \notin I} |c_{\mathbf{k}}| + \sum_{\mathbf{k} \in I} |c_{\mathbf{k}} - \hat{u}_{\mathbf{k}}| \right). \end{aligned}$$

Note that the bound constant B depends on the BOPB and therefore on the space $\mathcal H$ of our approximation. As an example, consider the well-known Fourier system using trigonometric polynomials $\exp(2\pi \mathrm{i}\langle \boldsymbol{k},\cdot\rangle)$ as basis functions, which comes with the bound constant B=1 independent of the dimension d. For the Chebyshev basis introduced in Section 1, the bound constant is $B=2^{d/2}$. If the considered approximation problem has a limited number of

interacting dimensions $d_s \leq d$, then the effective bound constant can be replaced with $B = 2^{d_s/2}$ instead.

The terms inside the brackets, which we will refer to as the truncation error $\sum_{{\boldsymbol k} \not \in I} |c_{\boldsymbol k}|$, and the coefficient approximation error $\sum_{{\boldsymbol k} \in I} |c_{\boldsymbol k} - \hat u_{\boldsymbol k}|$ are mainly influenced by the index set I and the approximated coefficients $\hat u_{\boldsymbol k}$. Hence, we not only need to compute good approximations of the coefficients $c_{\boldsymbol k}$ but also to detect a "good" index set I, hopefully containing the largest (in terms of absolute value) coefficients $c_{\boldsymbol k}$, to make (2.4) a reasonable approximation of the solution u.

2.3. The dimension-incremental method. In the present work, we will use the nonlinear approximation method for high-dimensional function approximation proposed in [24] in order to receive the desired approximation (2.4). First, we summarize some main aspects of the dimension-incremental algorithm here and refer to [24, Sec. 2] for more detailed explanations and proper definitions of the used notations. A simplified version of the algorithm is also given in Algorithm 1.

Suppose now for simplicity that we are interested in the approximation of a d-dimensional target function $g:\mathcal{D}\to\mathbb{C}$ of the form $g=\sum_{\boldsymbol{k}\in I}\hat{g}_{\boldsymbol{k}}\Phi_{\boldsymbol{k}}$ with the unknown index set $I\subset\mathbb{N}^d$. Later, the target function g will be the solution u in d+n dimensions. Motivated by the estimate above, we aim for an s-sparse index set I, i.e., |I|=s, corresponding to basis coefficients $c_{\boldsymbol{k}}$ with large absolute values.

Roughly, the algorithm uses samples of g to detect reasonable indices k_j of $\mathbf{k} = (k_j)_{j=1}^d$, $\mathbf{k} \in I$, in each dimension $j = 1, \ldots, d$ and reasonable combinations thereof. In order to do so, only a search space $\Gamma \supset I$ is needed in advance. Commonly, we choose search spaces like the full (non-negative) grid $\Gamma = [0, N]^d$ with some parameter $N \in \mathbb{N}$, which we will call an extension from now on. If there is additional initial knowledge of the structure of the desired index set I, then the choice of Γ can be improved.

The algorithm starts by investigating the one-dimensional projections given by $\mathcal{P}_{\{t\}}(\Gamma) \coloneqq \{k \in \mathbb{N} \mid \exists k \in \Gamma : k_t = k\}$, for all $t = 1, \ldots, d$, by constructing a suitable cubature rule for integrals of the form

(2.5)
$$\hat{g}_{\{t\},k_t}(\tilde{\boldsymbol{x}}) \coloneqq \int g(\xi,\tilde{\boldsymbol{x}})_{\{t\}} \overline{\Phi_{\{t\},k_t}(\xi)} d\xi,$$

with $\Phi_{\{t\},k_t}$ the one-dimensional basis function of the t-th dimension of our BOPB. The notation $g(\xi,\tilde{x})_{\{t\}}$ refers to sampling values of g using ξ in the t-th dimension and \tilde{x} for the remaining dimensions. The algorithm then computes these so-called projected coefficients $\hat{g}_{\{t\},k_t}$ using this cubature rule and the samples of the target function g for a particular random anchor \tilde{x} . The absolute value of these projected coefficients $\hat{g}_{\{t\},k_t}$ can be seen as an indicator whether or not k_t is important, i.e., if k_t should appear in the t-th component of any index $k \in I$. Hence, the algorithm takes the s (the sparsity) largest projected coefficients fulfilling $|\hat{g}_{\{t\},k_t}| \geq \delta_+$ for some initially chosen detection threshold δ_+ and adds the corresponding indices k_t to a temporary index set $I_{\{t\}}$. Since the computation of the projected coefficients $\hat{g}_{\{t\},k_t}$ involves randomness due to the randomly drawn anchor \tilde{x} , this computation is repeated r times with r being the number of detection iterations with different anchors $\tilde{x}^{(j)}$, $j=1,\ldots,r$.

The temporary index sets $I_{\{t\}}$ with the reasonable indices for each dimension $t=1,\ldots,d$ are now combined to proceed in a dimension-incremental way. Starting with t=2, a new candidate set $K:=(I_{\{1,\ldots,t-1\}}\times I_{\{t\}})\cap \mathcal{P}_{\{1,\ldots,t\}}(\Gamma)$ is formed, containing now higher-dimensional indices $\mathbf{k}\in\mathbb{N}^{|\{1,\ldots,t\}|}$. Again, a suitable t-dimensional cubature method, e.g., multiple rank-1 lattices as in [21], is constructed and evaluated using samples of the target

function g to compute the projected coefficients

$$\hat{g}_{\{1,...,t\},\boldsymbol{k}}(\tilde{\boldsymbol{x}})\coloneqq\int g(\boldsymbol{\xi},\tilde{\boldsymbol{x}})\overline{\Phi_{\{1,...,t\},\boldsymbol{k}}(\boldsymbol{\xi})}\mathrm{d}\boldsymbol{\xi},$$

for the indices $k \in K$, which is the natural generalization of (2.5) to multiple dimensions $\{1,\ldots,t\}$. As before, the algorithm collects those indices $k \in \mathbb{N}^t$ with the s largest (in absolute value) projected coefficients $\hat{g}_{\{1,\ldots,t\},k}$ in the temporary index set $I_{\{1,\ldots,t\}}$. These indices are now the tuples that can still appear in the first t components of the indices in the final index set I. If t < d holds, then this process is again influenced by the randomly chosen anchor \tilde{x} and therefore repeated r times. This process is then repeated with t+1 instead of t until t=d, where the projected coefficients $\hat{g}_{\{1,\ldots,d\},k}$ no longer depend on a random anchor \tilde{x} at all. We finally set $I=I_{\{1,\ldots,d\}}$ and $\hat{g}_k=\hat{g}_{\{1,\ldots,d\},k}$ for all $k\in I_{\{1,\ldots,d\}}$. The final output of the algorithm includes the desired index set I and the approximations \hat{g}_k of the true basis coefficients for each $k\in I$.

A crucial requirement for this algorithm is the access of the sampling values g(x) for arbitrary x in the algorithm, e.g., by a black-box function handler of g. This is because the necessary sampling points x, for which the corresponding sampling values g(x) are needed, are not known a priori but are computed adaptively during the algorithm based on the current candidate sets K and the constructed cubature methods, combined with the random anchors \tilde{x} . We again encourage the reader to consult [24] for a more detailed and rigorous explanation of this concept, the theorem on the theoretical detection guarantee, and simple numerical examples as well as several comments and discussions on the capabilities and restrictions of this algorithm. Further, similar approaches as in [39, Sec. 3.1.2] for the selection of the largest projected coefficients $\hat{g}_{\{1,\dots,t\},k}(\tilde{x})$ of the candidate sets K in each step might speed up these detections and therefore the whole algorithm if additional information on the behavior of these projected coefficients is known.

2.4. Black-box sampling of the differential equation. For our application of Algorithm 1, we have u as the target function and hence sampling points of the form (x, a). Each "sample" u(x, a) is then the value of the solution u of (2.1) for a given parameter a, evaluated at the spatial point x. In order to receive such samples, we utilize numerical solvers, e.g., the finite element method. With the given parameter a, we can compute the (fixed) right-hand side function f, solve the differential equation for this particular f numerically, and evaluate the approximate solution at x.

Since the algorithm only requires the final sampling value u(x, a), the choice of the particular method or numerical solver for the differential equation is completely free, as long as the approximated sampling value that we compute and return to the algorithm is a reasonable approximation of the true value u(x, a). This non-intrusive behavior of our algorithm is the reason for its generality. The properties of the differential equation (2.1) as well as possible difficulties therein are mostly dealt with by the numerical solver. As long as there is any possibility to obtain reasonable estimates of u(x, a) for a given (x, a), we can plug this method into our black-box sampling step. Note that while the accuracy and efficiency of the used numerical solver directly affect the accuracy and efficiency of our dimension-incremental method, we will not investigate the properties of these solvers in more detail in this work.

REMARK 2.1. Generally, the product-type domain \mathcal{D} , where we can apply Algorithm 1, will not coincide with the domain $\overline{\Omega} \times \mathbb{C}^n$ of our solution u. Hence, we need to transform and/or restrict this domain carefully such that the sampling points given by our algorithm are suitable for the differential operator.

Since $\overline{\Omega}$ will be some compact domain for many applications, it is often enough to apply a simple transformation \mathcal{T} for the spatial variable x, e.g., the continuous and bijective linear

Algorithm 1 Dimension-incremental algorithm (simplified).

                                                  number of detection iterations
(Step 1) [Single component identification]
   for t := 1, ..., d do
       Set I_{\{t\}} := \emptyset.
       Compute a suitable cubature method for \mathcal{P}_{\{t\}}(\Gamma).
       for i := 1, ..., r do
          Draw a random anchor \tilde{x}.
          Sample g at the necessary sampling points (the cubature nodes combined with \tilde{x}).
          Compute the projected coefficients \hat{g}_{\{t\},k_t}(\tilde{x}) for k_t \in \mathcal{P}_{\{t\}}(\Gamma).
          Add the (up to) s indices k_t with the largest proj. coef. |\hat{g}_{\{t\},k_t}(\tilde{x})| \geq \delta_+ to I_{\{t\}}.
       end for i
   end for t
(Step 2) [Coupled component identification]
   for t := 2, ..., d do
       If t < d, set \tilde{r} := r and otherwise \tilde{r} := 1.
       Set I_{\{1,...,t\}} := \emptyset.
       Construct the index set K := (I_{\{1,\ldots,t-1\}} \times I_{\{t\}}) \cap \mathcal{P}_{\{1,\ldots,t\}}(\Gamma).
       Compute a suitable cubature method for K.
       for i := 1, \ldots, \tilde{r} do
          Draw a random anchor \tilde{x}.
          Sample q at the necessary sampling points (the cubature nodes combined with \tilde{x} if t < d).
          Compute the projected coefficients \hat{g}_{\{1,...,t\},k}(\tilde{x}) for k \in K.
          Add the (up to) s indices k with the largest proj. coef. |\hat{g}_{\{1,...,t\},k}(\tilde{x})| \ge \delta_+ to I_{\{1,...,t\}}.
       end for i
   end for t
(Step 3)
   Set I := I_{\{1,...,d\}} and \hat{g}_{k} := \hat{g}_{\{1,...,d\},k} for all k \in I_{\{1,...,d\}}.
                    I \subset \Gamma \subset \mathbb{N}^d
  Output:
                                                 detected index set
                    (\hat{g}_{k})_{k\in I}\in\mathbb{C}^{|I|}
                                                 approximated coefficients with |\hat{g}_{k}| \geq \delta_{+}
```

transformation $\mathcal{T} \boldsymbol{x} = m_1 \boldsymbol{x} + m_2 \boldsymbol{1}$ with two constants $m_1, m_2 \in \mathbb{R}$, mapping \boldsymbol{x} to the desired domain $\overline{\Omega}$.

On the other hand, the parameters $a \in \mathbb{C}^n$ are more difficult to handle. In this case, we will often have to restrict the domain of a to, e.g., some compact interval again, before thinking about possible transformations as we did for the spatial part. This is obviously a loss of generality, and the restriction needs to be performed carefully such that the most reasonable source functions f can still be approximated well enough using the restricted a.

For examples of such transformations and restrictions, we refer to the particular examples in the following section.

REMARK 2.2. While we stick to the mentioned setting (2.1) for the theoretical part of this paper to preserve clarity in the notations, our numerical experiments in Section 3 also include some further variations, which we will only briefly mention in the following.

First, we can also consider parameterized differential operators \mathcal{L}_{θ} with some parameter $\theta \in \mathbb{R}^{n_{\theta}}, n_{\theta} \in \mathbb{N}$, and the corresponding solution mapping $\mathcal{G} : \mathcal{F} \times \mathbb{R}^{n} \to \mathcal{U}$. Correspond-

ingly, (2.3) then becomes

(2.6)
$$u(\boldsymbol{x}, \boldsymbol{a}, \boldsymbol{\theta}) := \sum_{\boldsymbol{k} \in \mathbb{N}^{d+n+n_{\theta}}} c_{\boldsymbol{k}} \Phi_{\boldsymbol{k}}(\boldsymbol{x}, \boldsymbol{a}, \boldsymbol{\theta}),$$

with another separable Hilbert space \mathcal{H} and corresponding BOPB $\{\Phi_{k}: k \in \mathbb{N}^{d+n+n_{\theta}}\}$. The truncated and approximated version (2.4) is then modified in the same way, now with an unknown index set $I \subset \mathbb{N}^{d+n+n_{\theta}}$. An example of this variation can be found in Section 3.4.

Similarly, we can consider time-dependent differential operators $\mathcal L$ with respect to some time variable $\tau \in [0,T]$ and their corresponding solution mapping $\mathcal G: \mathcal F \times [0,T] \to \mathcal U$. As before, we end up with the representation

$$u(\boldsymbol{x}, \tau, \boldsymbol{a}) \coloneqq \sum_{\boldsymbol{k} \in \mathbb{N}^{d+1+n_{\theta}}} c_{\boldsymbol{k}} \Phi_{\boldsymbol{k}}(\boldsymbol{x}, \tau, \boldsymbol{a})$$

and proceed similarly as above, now with the (d+1+n)-dimensional separable Hilbert space \mathcal{H} and an unknown index set $I\subset \mathbb{N}^{d+1+n}$.

In each case, we proceed to the approximation $S_I^A u$ from (2.4). This time, the analysis of the index set I and the coefficients \hat{u}_k can give additional information about the dependence and interaction of the spatial variable x and the right-hand side f, not only with each other but also with the parameters θ or the time variable t.

Obviously, a combination of these two variations, i.e., a parameter- and time-dependent differential equation, can be treated in an analogous way; cf. Section 3.5 with the one-dimensional heat equation.

3. Numerics. In this section, we test our approach on several test problems, such as multiple diffusion equations and the Burgers' equation, and discuss the results. We show that our approach leads to sparse index sets I that can be used directly for the high-dimensional approximation of the solution u or further generalized to even higher-dimensional problems. We will briefly investigate such a generalization for the first model example at the end of Section 3.1.1. For the other examples, we focus on the detection of a suitable index set I and omit the generalization to higher dimensions since the first part is the main goal of Algorithm 1.

As mentioned in Section 2, we need to choose a suitable BOPB for the solution u to achieve the basis expansion (2.3). In all of the following examples, we will work with the tensorized Chebyshev polynomials

$$T_{\boldsymbol{k}}(\boldsymbol{z}) \coloneqq \prod_{j=1}^{d+n} T_{k_j}(z_j), \quad \text{with} \quad T_{k_j}(z_j) = \begin{cases} 1 & k_j = 0, \\ \sqrt{2}\cos(k_j\arccos(z_j)) & k_j \neq 0, \end{cases}$$

on the domain $\mathcal{D}=[-1,1]^{d+n}$ as used in [24]. Hence, the approximation (2.4), inserting $\boldsymbol{z}:=(\boldsymbol{x},\boldsymbol{a})$ with $\boldsymbol{x}\in\mathbb{R}^d$ and $\boldsymbol{a}\in\mathbb{C}^n$, becomes

(3.1)
$$S_I^{\mathcal{A}} u(\boldsymbol{x}, \boldsymbol{a}) = \sum_{\boldsymbol{k} \in I} \hat{u}_{\boldsymbol{k}} T_{\boldsymbol{k}}(\boldsymbol{x}, \boldsymbol{a}),$$

where $I \subset \mathbb{N}^{d+n}$ is the detected index set and \hat{u}_k are the approximations of the corresponding exact basis coefficients c_k from (2.3).

To investigate the accuracy of our method, we consider, for a fixed coefficient $a \in \mathbb{C}^n$, the relative ℓ_2 -error

(3.2)
$$\operatorname{err}(\boldsymbol{a}) := \frac{\left\|S_I^{\mathcal{A}} u(\boldsymbol{x}, \boldsymbol{a}) - u(\boldsymbol{x}, \boldsymbol{a})\right\|_{\ell_2}}{\left\|u(\boldsymbol{x}, \boldsymbol{a})\right\|_{\ell_2}} = \frac{\left(\sum_{j=1}^G \left|S_I^{\mathcal{A}} u(\boldsymbol{x}^{(j)}, \boldsymbol{a}) - u(\boldsymbol{x}^{(j)}, \boldsymbol{a})\right|^2\right)^{\frac{1}{2}}}{\left(\sum_{j=1}^G \left|u(\boldsymbol{x}^{(j)}, \boldsymbol{a})\right|^2\right)^{\frac{1}{2}}},$$

where $x^{(j)}$, for $j=1,\ldots,G$, are equidistant grid points in the spatial domain Ω . We then proceed by computing this error for numerous, randomly drawn coefficients a and investigating the corresponding range as well as the first quartile, the median, and the second quartile of this statistical test (dividing the results into four equal parts).

All tests are performed in Python and can be found together with the algorithm in [36]. The overall runtime depends significantly on the specific problem, the desired accuracy, the chosen parameters, and the available computational resources. Therefore, the runtime for each example is briefly discussed in the corresponding sections. To accelerate the sampling process, we used parallelization with up to 180 separate cores but no GPU computing. If not stated otherwise, the dimension-incremental algorithm uses the following parameters and settings:

- the cubature method: Chebyshev multiple rank-1 lattices as described in [24, Sec. 4.2],
- the search space Γ : (non-negative) full grid $[0, N]^{d+n}$ in d+n dimensions with extension N and no superposition assumption,
- the detection threshold $\delta_{+} = 10^{-12}$,
- the number of detection iterations r = 5.

The sparsity s will be given for each test separately. See [24] for more detailed information on these parameters and settings and how they affect the behavior of the algorithm.

3.1. The one-dimensional Poisson equation. The following example considers a rather simple differential equation in order to first demonstrate the application of our proposed method.

Given a source function $f:(0,1)\to\mathbb{C}$, the one-dimensional Poisson equation with homogeneous Dirichlet boundary conditions reads as

(3.3)
$$-\frac{d^2}{dx^2}u(x) = f(x), \quad x \in (0,1),$$
$$u(0) = u(1) = 0.$$

For this differential operator $\mathcal{L}=-\frac{d^2}{dx^2}$ and these particular boundary conditions, we take the usual choice of function spaces $\mathcal{U}=H^1_0((0,1))$ and $\mathcal{F}=H^{-1}((0,1))$, the dual of $H^1_0((0,1))$. As described in Section 2, our first step is to find a suitable parameterization (2.2) of the function f. For this first example, we will consider two different approaches here:

- \bullet a parameterization of the source function f by its first Fourier coefficients,
- ullet a parameterization of the source function f by a B-spline approximation.

In all of these cases we restrict ourselves to a discretization of f using only n parameters. Together with the spatial dimension d=1, it results in an (n+1)-dimensional approximation problem. While choosing a larger n should lead to more accurate approximations of f and thus to a better quality of the approximation $S_I^{\mathcal{A}}u$ for general f, the additional dimensions will also result in higher sampling and computational complexities. Therefore, we have to choose reasonable limits for n in the upcoming examples.

3.1.1. Fourier series parameterization. We consider a parameterization of the source function f by its first $n \in 2\mathbb{N} + 1$ Fourier coefficients $\mathbf{a} = (a_{-\frac{n-1}{2}}, \dots, a_{\frac{n-1}{2}}) \in \mathbb{C}^n$, i.e.,

(3.4)
$$f(x) \approx \sum_{\ell = -\frac{n-1}{2}}^{\frac{n-1}{2}} a_{\ell} e^{2\pi i \ell x}.$$

These Fourier coefficients a can be computed efficiently for reasonable functions f using the well-known FFT. Note that this approximation of f will always be 1-periodic, forcing the implicit assumption that the function f is either a 1-periodic function itself or can be fairly well approximated by such a function.

Using this truncated Fourier series as the right-hand side of the differential equation (3.3), the solution u of the one-dimensional Poisson equation is then given analytically by

(3.5)
$$u(x, \mathbf{a}) = \frac{a_0}{2}x(1 - x) + \sum_{\substack{\ell = -\frac{n-1}{2} \\ \ell \neq 0}}^{\frac{n-1}{2}} \frac{a_\ell}{4\pi^2 \ell^2} (e^{2\pi i \ell x} - 1).$$

This formula can be used directly as the black-box sampling strategy necessary for our algorithm (see Section 2.4) to generate the necessary sampling values $u(x^*, a^*)$ for any sampling point (x^*, a^*) . To demonstrate the general application of Algorithm 1, we use this direct method to avoid errors made when solving the differential equation numerically and focus on the approximation of the solution u directly.

As mentioned in Remark 2.1, we need to pay attention since the original domain $[0,1] \times \mathbb{C}^n$ does not match our function approximation domain $\mathcal{D} = [-1,1]^{n+1}$. For the spatial part, we apply the transformation $\mathcal{T}x = \frac{1}{2}(x+1)$ to perform the shift between [-1,1] and [0,1]. For simplicity, we directly assume the restriction $a \in [-1,1]^n$ for the Fourier coefficients a such that we can omit further transformations. Note that this implies that we are only interested in right-hand side functions f that can be well approximated by using such Fourier coefficients a in this artificial example. Overall, the final function that we are going to approximate here is now

$$\tilde{u}(\tilde{x}, \boldsymbol{a}) := u(\mathcal{T}\tilde{x}, \boldsymbol{a}) = u\left(\frac{1}{2}(\tilde{x}+1), \boldsymbol{a}\right), \quad \tilde{x} \in [-1, 1], \, \boldsymbol{a} \in [-1, 1]^n.$$

Using the explicit formula (3.5), we get

(3.6)
$$\tilde{u}(\tilde{x}, \boldsymbol{a}) = \frac{a_0}{8} (1 - \tilde{x}^2) + \sum_{\substack{\ell = -\frac{n-1}{2} \\ \ell \neq 0}}^{\frac{n-1}{2}} \frac{a_\ell}{4\pi^2 \ell^2} ((-1)^\ell e^{\pi i \ell \tilde{x}} - 1).$$

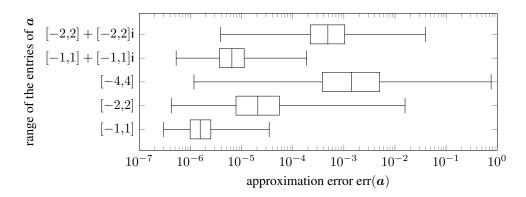

FIG. 3.1. The relative approximation error $err(\mathbf{a})$ for 10000 randomly drawn \mathbf{a} when using the Fourier series parameterization. The box-and-whisker plots show the median, the first and the second quartile, as well as the maximal and minimal error observed. The five plots indicate different choices for the range of the Fourier coefficient \mathbf{a} , including two cases with complex-valued Fourier coefficients. The range [-1,1] coincides with the training data used

the high-dimensional torus domain $\mathcal{D}=\mathbb{T}^{n+1}$ as well as a Fourier basis for the approximation space \mathcal{H} . We use n=9 as the number of Fourier coefficients a_ℓ for our tests, which results in the overall dimension d+n=10. Further, we choose the sparsity s=1000 and the extension N=64 of the search space Γ . Since we do not use a numerical solver but the exact solution, each solution sample can be generated in about 10^{-4} seconds, resulting in an overall runtime of our algorithm of about 2 minutes.

The accuracy of our approximation is shown in Figure 3.1. Therein, we used 10000 randomly drawn Fourier coefficients a and computed the relative ℓ_2 -error $\operatorname{err}(a)$ using G=1000 equidistant grid points in the spatial domain. We use box-and-whisker plots to illustrate the statistical distribution here, where the central line inside the box indicates the median. On each side of the median, the box contains 25% of the data. Outside the box, the whiskers indicate the maximal and minimal error observed. Since we did not specify outliers in our data, the box-and-whisker plot truly covers the full range of observed errors.

The first plot with the range [-1,1] is the true approximation error since the same range for the entries of a is used as we did during our approximation. Although the computed coefficients \hat{u}_k from (3.1) smaller than 10^{-7} are not necessarily true basis coefficients but mainly artifacts because of numerical errors, the overall approximation accuracy is still satisfactory. The other plots in Figure 3.1 show results with larger or even complex domains for the test Fourier coefficients a. For this transfer learning scenario, it shows that our approximation is also applicable for slightly larger domains of a, and therefore for more source functions f, than the restricted ones from the training setting. However, the further the test cases are from the training setting, the larger our relative approximation error $\operatorname{err}(a)$ grows. Thus, we strongly recommend using another restriction $a \in [-\alpha, \alpha]^n$, a > 1, and transform the domain similarly to the spatial variable a already in the training process, if the desired functions a require such Fourier coefficients a.

The detected indices show a clear structure as can be seen for the first indices in Figure 3.2. For all dimensions corresponding to an entry of the Fourier coefficient vector \boldsymbol{a} , there exists no other entry than 0 or 1. This effect is not caused by the particular sparsity s that we have chosen since the algorithm already neglects every other possible entry (the numbers from 2 to 64 for our choice of N) in the single component identification step (cf. Step 1 in Algorithm 1) such that they can not appear at all in these dimensions. This result is exactly what we expected knowing the explicit formula (3.6) since therein all the Fourier coefficients a_{-4}, \ldots, a_4 appear

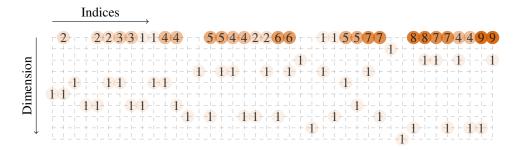

FIG. 3.2. An abstract visualization of the first 40 indices \mathbf{k} detected when using the Fourier series parameterization. The leftmost column contains the index \mathbf{k} corresponding to the largest (in absolute value) basis coefficient $\hat{u}_{\mathbf{k}}$, the second column the index for the second largest, and so on. The rows identify the 10 dimensions corresponding to the variables x and a_{-4}, \ldots, a_4 from top to bottom in this order. Zeros are neglected to preserve clarity.

only linearly. Additionally, the only indices where the entry corresponding to a_0 is non-zero are the first and second ones, which can be seen in Figure 3.2 as the first and second columns. Again, this matches our expectations since a_0 only appears in the first term of (3.6), which can be rewritten in terms of the Chebyshev polynomials as

$$\frac{a_0}{8}(1-\tilde{x}^2) = \frac{1}{8\sqrt{2}}T_1(a_0)\left(\frac{1}{2}T_0(x) - \frac{1}{2\sqrt{2}}T_2(x)\right) \prod_{\substack{\ell = -\frac{n-1}{2} \\ \ell \neq 0}}^{\frac{n-1}{2}} T_0(a_\ell)$$

$$= \frac{1}{16\sqrt{2}}T_{\mathbf{k}^{(1)}}(x, \mathbf{a}) - \frac{1}{32}T_{\mathbf{k}^{(2)}}(x, \mathbf{a}),$$

with

$$\boldsymbol{k}^{(1)} = [\underbrace{0}_{T_0(x)}, \underbrace{0, 0, 0, 0}_{T_0(a_{\ell})}, \underbrace{1}_{T_1(a_0)}, \underbrace{0, 0, 0, 0}_{T_0(a_{\ell})}]^T$$

and

$$\boldsymbol{k}^{(2)} = [\underbrace{2}_{T_2(x)}, \underbrace{0, 0, 0, 0}_{T_0(a_{\ell})}, \underbrace{1}_{T_1(a_0)}, \underbrace{0, 0, 0, 0}_{T_0(a_{\ell})}]^T$$

being the indices mentioned above. Finally, we would expect no couplings between the different Fourier coefficients a_{-4},\ldots,a_4 since they never appear together in the parts of the sum in the right-hand side of (3.6). While this behavior can be observed for the first detected indices in Figure 3.2, this does not hold for all of our detected indices. At some point, the values of the remaining true Chebyshev coefficients become so small that the algorithm can not distinguish their corresponding indices from false ones like $[2,1,0,1,1,1,0,1,0,1]^T$, which seems to produce similar coefficient values due to small numerical errors. However, since the size of the coefficients where this effect happens is already very small, i.e., about 10^{-8} , this does not harm the overall approximation. Obviously, this minor problem is simply caused by the large sparsity s=1000 and could also be prevented up to some extent by using a search space Γ that does not contain indices k with so many non-zero entries.

EXAMPLE 3.2 (High-dimensional extension of the detected index set I). As stated already in Section 1, we can use the structure of the detected index set I to extend our approach to even

higher dimensions. We demonstrate this approach here for the current differential equation with the Fourier series parameterization due to its simple structure and our explicit knowledge of the true solution (3.6).

APPROACH TO DISCRETE OPERATOR LEARNING VIA SPARSE APPROXIMATION

We increase n, the number of Fourier coefficients a_ℓ used, to 99 in order to achieve a better resolution of the right-hand side function f than before. Obviously, this leads us to the approximation of the now 100-dimensional function u(x, a). However, analyzing the detected index set I from our 10-dimensional test above, we can construct a good index set I directly by generalizing the main structural features of I. In detail, we will construct our new index set I in the following way:

- The first dimension (corresponding to the spatial variable x) may contain any number from 0 to N_x .
- The entries of the dimensions 2 to 100 are either all zero or contain at most one non-zero entry. This non-zero entry, if existing, must be 1.

This index set I then contains $(N_x + 1) \cdot 100$ indices of a similar structure as in Figure 3.2. Note that we did not include the fact that there were only two indices $k^{(1)}$ and $k^{(2)}$ with a non-zero entry in the dimension corresponding to a_0 .

We perform our test using $N_x=999$, so we are using an index set I containing 10^5 indices k. We compute the corresponding basis coefficients u_k by the same Chebyshev multiple rank-1 lattice approach from [22] as before in Algorithm 1. Our full dimensionincremental algorithm in just 10 dimensions already needed around 400000 samples for this simple example. Now we only need about 300000 samples to approximate all the basis coefficients $\hat{u}_k, k \in I$, in this 100-dimensional example. This would be an impossible goal when applying Algorithm 1 directly to the 100-dimensional approximation problem instead. Especially for real applications, where the sampling values are not generated by an explicit formula but by a differential equation solver (like the FEM), the reduction of the amount of samples needed is an important tool since the corresponding calls of the differential equation solver will be the dominating part of the computational complexity of the whole algorithm. The same problem appeared in [23] and was the main motivation for the method proposed there. The relative approximation errors range from 10^{-8} to at most 10^{-6} , which is a further improvement compared to the relative errors for the range [-1, 1] in Figure 3.1. Note that all these tests were performed with right-hand side functions f of the form (3.4), so as before there was no error in the discretization of this function. However, the higher resolution of this approach with n = 99 allows for a much better discretization error (of the function f) if we work with more general right-hand side functions f.

3.1.2. B-spline parameterization. We approximate the right-hand side f by a sum of n B-splines, i.e.,

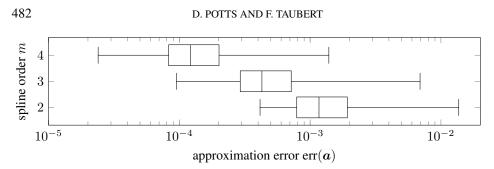

$$f(x) \approx \sum_{\ell=0}^{n-1} a_{\ell} B_{\ell}^{(m)}(x),$$

where $B_\ell^{(m)}$ are versions of the cardinal B-spline $B^{(m)}$ of order m. Originally, they are recursively defined via

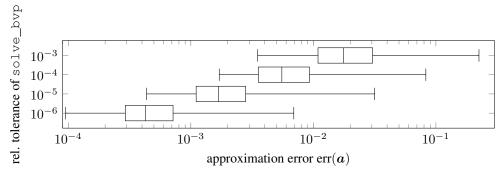

$$B^{(1)}(x) \coloneqq \begin{cases} 1 & -\frac{1}{2} < x < \frac{1}{2}, \\ 0 & \text{otherwise}, \end{cases} \quad \text{and} \quad B^{(m)}(x) \coloneqq \int_{x-\frac{1}{2}}^{x+\frac{1}{2}} B^{(m-1)}(y) \mathrm{d}y.$$

We use the additional index ℓ to indicate that we scaled and shifted them with respect to the interval [0,1] and the desired number of B-splines n, such that their peaks are equidistantly spaced along the interval and each spline overlaps m-1 neighboring splines in each direction.

(a) Varying the spline order m for a fixed relative tolerance 10^{-6} (default).

(b) Varying the relative tolerance for a fixed spline order m=3.

Fig. 3.3. The relative approximation error err(a) for 10000 randomly drawn a for different choices of the spline order m and the relative tolerance of the solver function $solve_bvp$. The box-and-whisker plots show the median, the first and the second quartile, as well as the maximal and minimal error observed.

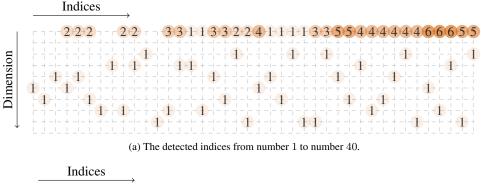

This time, we use a classical differential equation solver to acquire the sample values $u(x^*, \boldsymbol{a}^*)$ for any sampling point (x^*, \boldsymbol{a}^*) . In particular, we will apply the function solve_bvp from the submodule scipy.integrate here, which is capable of solving first-order systems of ODEs with two-point boundary conditions. As mentioned in Remark 2.1, we need to transform the points (x, \boldsymbol{a}) such that they fit in the domain $\mathcal{D} = [-1, 1]^{n+1}$. We perform the same steps as in the previous example by transforming $\mathcal{T}x = \frac{1}{2}(x+1)$ and restricting $\boldsymbol{a} \in [-1, 1]^n$ throughout this example. Hence, once again the final function that we are going to approximate is $\tilde{u}(\tilde{x}, \boldsymbol{a}) := u(\mathcal{T}\tilde{x}, \boldsymbol{a}) = u(\frac{1}{2}(\tilde{x}+1), \boldsymbol{a})$.

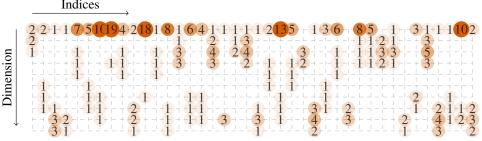

Additionally, we also use the same number n=9 of spline coefficients a_ℓ , again resulting in a 10-dimensional approximation problem. The sparsity s=1000 and the extension N=64 of the search space Γ also remain the same. With the differential equation solver needing roughly 0.1 seconds per call, we ended up with an overall runtime of our method of almost 6 hours.

The approximation error shown in Figure 3.3 is derived by evaluating our approximation as well as the solution given by the function $solve_bvp$ on 1000 equidistant spatial points and considering the respective ℓ_2 -error err(a). The reference solution for the error estimation was obtained by using a relative tolerance of 10^{-9} in $solve_bvp$. As in the previous example, we use box-and-whisker plots to visualize the statistical distribution of the results, i.e., the range and the median of the observed errors as well as their quartiles.

Figure 3.3a illustrates the results for different choices of the spline order m when parameterizing the right-hand side function f. The piecewise linear splines (m=2) result in rather unsatisfying errors, probably caused by the lack of smoothness. Higher-order splines with

APPROACH TO DISCRETE OPERATOR LEARNING VIA SPARSE APPROXIMATION

(b) The detected indices from number 201 to number 240.

FIG. 3.4. Abstract visualizations of 40 detected indices k (from left to right) for Example 3.1.2. The indices kare sorted in descending order according to the size of the corresponding approximated coefficient $\hat{u}_{\mathbf{k}}$. The rows identify the 10 dimensions corresponding to the variables x and a_{-4}, \ldots, a_4 from top to bottom in this order. Zeros are neglected to preserve clarity.

m=3 and m=4 provide better results, especially when investigating the range and the worst case of the possible errors err(a). Although the overall error size in Figure 3.3a might seem a bit large, it is matching the default relative tolerance 10^{-6} of the function solve_bvp, which we used for these tests. A lower accuracy of the underlying differential equation solver leads to a lower accuracy of our method, which can be observed in Figure 3.3b. Here, we fixed the spline order m=3 and varied the relative tolerance of the function solve_bvp. As mentioned before, we will not go into further detail about the properties of the differential equation solvers used. However, we wanted to briefly mention the influence of the accuracy of the underlying solver at least for this first example.

Figure 3.4a displays two parts of the detected index set I for the spline order m=3. As in Example 3.1.1, we notice a sparse structure of the first detected indices. This time we do not have an explicit representation of the true solution u and only use approximations of the solution given by the differential equation solver as our samples. Hence, we are not capable of comparing these indices and the corresponding values to the true ones as before. However, the structure, which can be observed in Figure 3.4a, is still highly reasonable. It shows that the algorithm is prioritizing two-dimensional couplings with small entries in the first dimension corresponding to the spatial variable x. For later indices as shown for example in Figure 3.4b, there appear some higher-dimensional couplings and even some values greater than 1 outside the spatial dimension. The coupling B-spline coefficients a_{ℓ} are always adjacent. This is caused by the overlapping nature of the B-splines. Even for later indices (apart from numerical errors as described below) this behavior will continue.

On the other hand, each of the 1000 detected indices contains at least one non-zero entry in the dimensions 2 to 10, i.e., the corresponding Chebyshev series does not contain a single term that depends only on x. Unfortunately, there are again some artifact indices as well, which do not contain a single zero entry but unreasonably large numbers (≥ 10) in these dimensions. As before, these are mainly caused by numerical errors and could be reduced by choosing the search space Γ more restrictively.

Finally, all the computed coefficients are real valued this time. While the domain of the coefficients a is the same as before, multiplying them with the cardinal B-splines instead of the Fourier terms causes the source function f and therefore also the solution u to be real valued for each possible coefficient a.

3.2. A piecewise continuous differential equation. As a second one-dimensional example, we consider the ordinary differential equation

(3.7)
$$-\frac{d}{dx}\left(a(x)\frac{d}{dx}u(x)\right) = f(x), \qquad x \in (-1,1),$$

$$u(-1) = u(1) = 0,$$

with the piecewise constant coefficient function

$$a(x) = \begin{cases} \frac{1}{2} & x \in (-1,0), \\ 1 & x \in [0,1). \end{cases}$$

This example was investigated in [34, Sec. 2.3] and caused tremendous problems when using physics-informed neural networks (PINNs) since it has no classical but only a weak solution u for the given right-hand side function f

(3.8)
$$f(x) = \begin{cases} 0 & x \in (-1,0), \\ -2 & x \in [0,1). \end{cases}$$

Therefore, we are interested in solving (3.7) using our approach and comparing the result for this particular right-hand side function f. The exact solution for this scenario is also given in [34] as

(3.9)
$$u(x) = \begin{cases} -\frac{2}{3}x - \frac{2}{3} & x \in (-1,0), \\ x^2 - \frac{1}{3}x - \frac{2}{3} & x \in [0,1). \end{cases}$$

The differential operator for this ODE is $\mathcal{L}=-\frac{d}{dx}a(x)\frac{d}{dx}$. We choose $\mathcal{U}=H^1_0((-1,1))$ and $\mathcal{F}=H^{-1}((-1,1))$ as the function spaces, the approximation domain $\mathcal{D}=[-1,1]^{n+1}$, and the tensorized Chebyshev polynomials as the BOPB. In order to resolve (3.8) properly, we choose a discretization of f similar to Section 3.1.2 using B-splines of order m=1 and characteristic functions on non-overlapping intervals. Precisely, we resolve the right-hand side f as

$$f(x) = \sum_{\ell=0}^{7} b_{\ell} \mathbb{1}_{\left[-1 + \frac{\ell}{4}, -1 + \frac{\ell+1}{4}\right]}(x),$$

such that the particular function f given in (3.8) is obtained exactly for the spline coefficients $\mathbf{b} = [0, 0, 0, 0, -2, -2, -2, -2]^T$. Then, the general exact solution reads as

(3.10)
$$u(x, \mathbf{b}) = \begin{cases} \sum_{\ell=0}^{7} -2b_{\ell}W_{\ell}(x) + 2C_{1}x + C_{2} & x \in (-1, 0), \\ \sum_{\ell=0}^{7} -b_{\ell}W_{\ell}(x) + C_{1}x + C_{2} & x \in [0, 1), \end{cases}$$

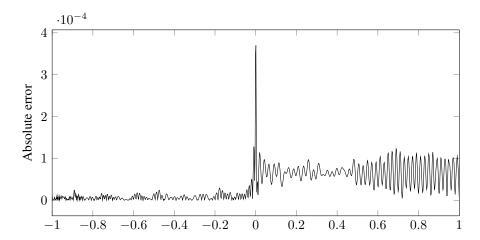

FIG. 3.5. The absolute pointwise approximation error of our approximation when using the right-hand side (3.8) compared to the exact solution (3.9).

with

$$W_{\ell}(x) \coloneqq \begin{cases} 0 & x \in (-1, -1 + \frac{\ell}{4}), \\ \frac{1}{2}x^2 + (1 - \frac{\ell}{4})x + \frac{1}{2}(-1 + \frac{\ell}{4})^2 & x \in [-1 + \frac{\ell}{4}, -1 + \frac{\ell+1}{4}), \\ \frac{1}{4}x + \frac{7}{32} - \frac{\ell}{16}, & x \in [-1 + \frac{\ell+1}{4}, 1) \end{cases}$$

being the second anti-derivative of the characteristic function $\mathbb{1}_{[-1+\frac{\ell}{4},-1+\frac{\ell+1}{4}]}(x)$. The boundary conditions from (3.7) yield $C_2=2C_1$ and $C_1=\sum_{\ell=0}^7 b_\ell \frac{15-2\ell}{96}$.

To obtain the necessary samples of the (weak) solution of (3.7), we utilize the popular open-source computing platform FEniCS and its Python interface. The underlying finite element method is very well capable of computing the weak solution of (3.7), making it a perfect tool for our black-box sampling step. We use a rather coarse mesh with only 100 nodes. Note that the domain of the spatial variable x is this time already [-1,1] and thus needs no further transformation. On the other hand, we scale the spline coefficients b_{ℓ} with a factor of 2 (or $\frac{1}{2}$, respectively) to cover the range $[-2,2]^8$, such that the particular right-hand side f given in (3.8) can be resolved exactly as described above.

The number n=8 of spline coefficients b_ℓ is already fixed such that we have the overall dimension d=9 for this problem. We use the sparsity s=4000 with the extension N=256 for this test example. The dimension-incremental method needed about 75 minutes for this approach. FEniCS itself computes one solution sample for this problem in about 10^{-2} seconds.

Figure 3.5 illustrates the pointwise error of our approximation for the particular function f given in (3.8) when compared to the true solution (3.9). We note that the kink of the exact solution u at the point x=0 leads to larger pointwise errors in this region, which is not surprising given our smooth basis functions and hence the smoothness of our approximation. Further, it appears that in the right half of the domain, the pointwise errors are no longer unbiased but oscillate around some constant greater than zero.

The detected index set, partially illustrated in Figure 3.6, shows the usual structure from the previous example. The linear dependence of the spline coefficients \boldsymbol{b} in the analytical solution (3.10) is detected perfectly, neglecting any entries larger than 1 in these dimensions already in Step 1 of Algorithm 1. This is highly remarkable when compared to our first example in Section 3.1.1 since we are using a numerical solver instead of an analytical solution this time. So while the samples of the solution u contain small numerical errors, our algorithm

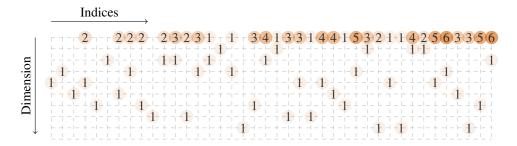

FIG. 3.6. An abstract visualization of the first 40 indices k detected for the piecewise continuous differential equation example. The indices k are ordered by the absolute values of their corresponding approximated coefficients \hat{u}_k in descending order from left to right. The rows identify the 9 dimensions corresponding to the spatial variable x and the x0 spline coefficients x0 used. Zeros are neglected to preserve clarity.

still successfully neglects the unnecessary values in Step 1. The first dimension, corresponding to the spatial variable x, contains again larger values, caused by the highly piecewise structure of the solution (3.10).

3.3. The multi-dimensional Poisson equation. While in the previous examples we have considered ordinary differential equations, we now proceed to partial differential equations with the two-dimensional version of (3.3). The general Poisson equation with homogeneous Dirichlet boundary conditions is given by

(3.11)
$$\begin{aligned} -\Delta u(\boldsymbol{x}) &= f(\boldsymbol{x}), & \boldsymbol{x} \in \Omega, \\ u(\boldsymbol{x}) &= 0, & \boldsymbol{x} \in \delta\Omega, \end{aligned}$$

with the spatial domain $\Omega=(0,1)^d$. We restrict ourselves to the two-dimensional version d=2 in this work, while d=3 is also a common setting in applications. With the differential operator $\mathcal{L}=-\Delta$ and the homogeneous Dirichlet boundary conditions, we use the common function spaces $\mathcal{U}=H^1_0(\Omega)$ and $\mathcal{F}=H^{-1}(\Omega)$, which is the direct generalization of the function spaces used in Section 3.1. Also, the approximation space $\mathcal{H}=L_2(\mathcal{D})$ is again equipped with the tensorized Chebyshev polynomials on the now (n+2)-dimensional domain $\mathcal{D}=[-1,1]^{n+2}$.

Motivated by the example from Section 3.1, we use a two-dimensional Fourier series to parameterize the right-hand side function f in this example. In detail, we parameterize f by

$$f(x) \approx \sum_{\ell \in J} a_{\ell} e^{2\pi i \ell x},$$

with the index set J, again containing a total of n indices. As in the one-dimensional case, this choice should result in a rather simple detected index set I when applying our algorithm.

As in Section 3.2, we use FEniCS to solve the PDE (3.11) with the finite element method for a given a. For the finite element mesh, we used a uniform unit square mesh with 51 equidistant points in each direction. Since each square cell is split into two triangular elements, we thus end up with 5000 elements for our approximation. As in the ODE examples, we still need to transform the sampling points (x, a). Hence, we proceed similarly as in Section 3.1.1 by using the transformation $\mathcal{T}x = \frac{1}{2}(x+1)$ and simply restricting $a \in [-1,1]^n$.

We set $J=\{-1,0,1\}^2$ in order to have n=9 Fourier coefficients. Combined with the spatial dimension d=2, this time we end up with an 11-dimensional approximation problem. Further, we choose the sparsity s=1000 and the extension N=64 of the

APPROACH TO DISCRETE OPERATOR LEARNING VIA SPARSE APPROXIMATION

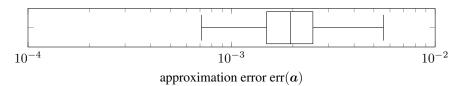

FIG. 3.7. The relative approximation error err(a) for 10000 randomly drawn a for the two-dimensional Poisson equation example. The box-and-whisker plots show the median, the first and the second quartile, as well as the maximal and minimal error observed.

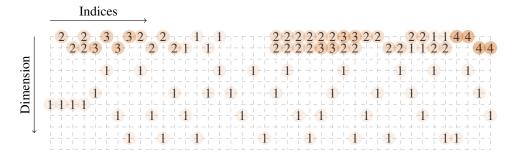

FIG. 3.8. An abstract visualization of the first 40 indices \mathbf{k} detected for the two-dimensional Poisson equation example. The indices \mathbf{k} are ordered by the absolute values of their corresponding approximated coefficients $\hat{u}_{\mathbf{k}}$ in descending order from left to right. The rows identify the 11 dimensions corresponding to the two spatial variables $\mathbf{x} = (x_1, x_2)^T$ and the n = 9 Fourier coefficients \mathbf{a} used. Zeros are neglected to preserve clarity.

search space Γ . FEniCS needs up to 3 seconds for each single solution this time, leaving our dimension-incremental method with a total runtime of roughly 100 minutes.

Figure 3.7 illustrates the relative approximation error $\operatorname{err}(a)$, as before in the one-dimensional case, using 10000 randomly drawn coefficients a. Note that this error is computed by comparing our approximation to the solution that the FEM solver produces for the given coefficients a on the nodes of the FE mesh using the same parameters as we did during the execution of our algorithm. We observe errors of sizes around 10^{-3} , which are obviously larger than before in Section 3.1.1. However, this effect is primarily caused by the fact that we are no longer using a direct representation of the analytic solution as for the one-dimensional example to generate our sampling points. The error sizes are still reasonable and can compete with the used PDE solver, taking into account the sparsity s and the extension s0 used here.

The structure of the detected index set I, where the first part is shown in Figure 3.8, is pretty similar to the one seen in Section 3.1.1. Even though we are not using the exact solution for our training samples anymore, our algorithm is still able to identify that, for the dimensions corresponding to the Fourier coefficients a, the only necessary entries are 0 and 1. The entries of the first two dimensions, corresponding to the spatial dimensions x, also contain larger numbers but are growing significantly slower than in the one-dimensional example. This is due to the fact that in this two-dimensional case all possible combinations of the entries in these two dimensions have to be exploited. Overall, the discovered structure resembles that one from our first example quite nicely and seems like the kind of structure of such an index set that we would expect as the canonical generalization to multi-dimensional examples even without examining an analytical solution.

3.4. A diffusion equation with an affine random coefficient. The differential equation (3.7) is also a one-dimensional diffusion equation where the coefficient a could be called

diffusion coefficient as well. Now, we investigate a two-dimensional diffusion equation on $\Omega = [0, 1]^2$ with a randomized diffusion coefficient a, which is not only a PDE instead of an ODE but also a parameterized differential equation, i.e.,

$$\begin{split} -\nabla \cdot (a(\boldsymbol{x}, \boldsymbol{y}) \nabla u(\boldsymbol{x}, \boldsymbol{y})) &= f(\boldsymbol{x}), \quad \boldsymbol{x} \in \Omega, \, \boldsymbol{y} \in \Omega_{\boldsymbol{y}}, \\ u(\boldsymbol{x}, \boldsymbol{y}) &= 0, \qquad \boldsymbol{x} \in \partial \Omega, \, \boldsymbol{y} \in \Omega_{\boldsymbol{y}}. \end{split}$$

Here, the differential operator ∇ is always applied to the spatial variable x. While there exist multiple kinds of randomized diffusion coefficients a, as can be seen for example in [23], we will only work with an affine random coefficient a here. In more detail, we consider the particular example from [10, Sec. 11], where we have, for $n_y = 20$, the affine coefficient

$$a(\boldsymbol{x}, \boldsymbol{y}) \coloneqq 1 + \sum_{j=1}^{n_{\boldsymbol{y}}} y_j \psi_j(\boldsymbol{x}), \qquad \boldsymbol{x} \in \Omega, \ \boldsymbol{y} \in [-1, 1]^{20}$$

with the random variables $\boldsymbol{y} \sim \mathcal{U}([-1,1]^{n_{\boldsymbol{y}}})$ and

$$\psi_j(\mathbf{x}) := cj^{-\mu} \cos(2\pi m_1(j) x_1) \cos(2\pi m_2(j) x_2), \quad \mathbf{x} \in \Omega, j \ge 1.$$

Here, c > 0 is a constant and $\mu > 1$ the decay rate. In our numerical example below, we use the values $c = 0.9/\zeta(2)$ and $\mu = 2$ also used in [10]. Further, $m_1(j)$ and $m_2(j)$ are defined as

$$m_1(j) := j - \frac{k(j)(k(j)+1)}{2}$$
 and $m_2(j) := k(j) - m_1(j)$,

with $k(j) := \lfloor -1/2 + \sqrt{1/4 + 2j} \rfloor$. For some explicit values of $m_1(j), m_2(j)$, and k(j) as well as for more details on this differential problem, see [10]. As before, we consider the common function spaces $\mathcal{U} = H_0^1(\Omega)$ and $\mathcal{F} = H^{-1}(\Omega)$ for this differential operator.

REMARK 3.3. We have already considered the numerical solution of this problem in [23, Sec. 4.3] using a slightly different approach. Therein, we discretize the spatial domain $\Omega = [0,1]^2$ and compute approximations like (2.6) with $\theta = y$ in the Fourier setting for every fixed node $x_g, g = 1, \ldots, G$. The key ingredient there is that the a priori unknown index set I is chosen similarly for each of the G approximations $S_I^A u(x_g, \cdot)$, which allows us to compute all these approximations using only a single call of a modification of the sparse approximation algorithm with slightly more samples and computation time needed. For a given random coefficient y^* , we then compute the values of $S_I^A u(x_g, y^*)$ at all the nodes x_g and interpolate between them to receive a solution on the complete domain Ω .

In contrast to all other examples considered in this work, we decided to use the fixed right-hand side $f\equiv 1$ without parameterization since we are mainly interested in a comparison with the results from [23]. Hence, we neglect the space $\mathcal F$ for this example and proceed with the solution operator $\mathcal G:\Omega_{\boldsymbol y}\to \mathcal U$ this time. The approximation space is still $\mathcal H=L_2(\mathcal D)$, again using the tensorized Chebyshev polynomials and $\mathcal D=[-1,1]^{n_{\boldsymbol y}+2}$. The random variables $\boldsymbol y$ already match with that domain, so we only transform $\boldsymbol x$ as usual using the transformation $\mathcal T\boldsymbol x=\frac12(\boldsymbol x+1)$. Note that one could still use a similar approach as in the previous examples to easily parameterize the right-hand side f as well in this example. As in Section 3.3, we utilize FEniCS to solve the differential equation using 5000 elements.

Since there is no parameterization of the right-hand side f but two spatial dimensions, as well as $n_{\boldsymbol{y}}=20$ dimensions for the random variable \boldsymbol{y} , we still end up with a total of 22 dimensions for our approximation problem. Unfortunately, the sampling complexity as well as the computational complexity of our approach using the Chebyshev basis include an exponential factor for the maximal number of non-zero entries of the indices \boldsymbol{k} appearing in

489

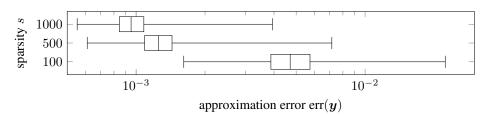

FIG. 3.9. The relative approximation error err(y) for 10000 randomly drawn variables y for the diffusion equation example for different sparsities s. The box-and-whisker plots show the median, the first and the second quartile, as well as the maximal and minimal error observed.

the candidate sets K during Step 2 of Algorithm 1. In order to prevent cases where numerical errors cause candidates k with (almost) all entries non-zero in any dimensions, we impose a superposition dimension $d_s=7$ on our 22-dimensional search space Γ with extension N=64 for this example. Unfortunately, the more difficult structure of the differential equation lead to a FEniCS computation time of up to 14 seconds per call, resulting in a total runtime of about 60 hours (for sparsity s=1000).

Figure 3.9 illustrates the relative approximation error $\operatorname{err}(y)$ for different sparsities s, this time with respect to the random variable y. As in the previous example, for getting comparison values, the error is computed using the solution of the FEM with the same settings. The error is again of reasonable size, even though this differential problem is significantly more difficult than the previous two-dimensional example in Section 3.3. Further, the largest nodal error as considered in [23, Sec. 4, Fig. 6], i.e., the largest error at any of the nodes of the FE mesh when evaluating the approximation for 10000 randomly drawn y and considering the respective ℓ_2 -norm, is just slightly larger than for the uniform sparse FFT from [23]. This small increase is probably caused by the fact that we are no longer focusing on particular nodes and basis expansions of the solution u at these nodes but using a full basis expansion of u, also considering the spatial variable.

The structure of the 22-dimensional index set is pretty similar to the previous examples and not illustrated here due to the high number of dimensions. Surprisingly, the range of the entries in the dimensions corresponding to the random variables y is rather restricted. Even in the one-dimensional detections (Step 1 in Algorithm 1), the algorithm cannot detect a full range of 65 possible entries (from 0 to N=64) and only detects less than 20 possible entries for y_1 , which decay rapidly down to only 4 possible entries (so 0, 1, 2, and 3) for the later dimensions like y_{15} . While we already saw the extreme version of this behavior for the Poisson equation using the Fourier series parameterization, where the only possible entries were 0 and 1, we did not observe anything similar for the other examples like in Section 3.1.2.

3.5. Heat equation. Our next example is the heat equation in one dimension with homogeneous boundary conditions on the domain $\Omega = (0, L)$, i.e.,

(3.12)
$$\partial_{\tau} u - \alpha^{2} \partial_{xx} u = 0, \qquad x \in (0, L), \ \tau \in (0, T),$$

$$u(x, 0) = f(x), \qquad x \in (0, L),$$

$$u(0, \tau) = u(L, \tau) = 0, \qquad \tau \in (0, T).$$

In this time-dependent differential equation, the source term on the right-hand side is zero and therefore does not require parameterization. Instead, our focus lies on the initial condition u(x,0)=f(x), which characterizes the system's state at the initial time $\tau=0$. Consequently, we aim to parameterize the function f.

D. POTTS AND F. TAUBERT

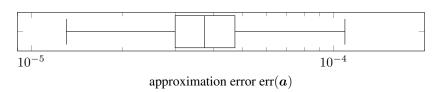

Fig. 3.10. The relative approximation $error\ err(a)$ for 10000 randomly drawn a for the heat equation example. The box-and-whisker plots show the median, the first and the second quartile, as well as the maximal and minimal error observed.

We are interested in the well-known solution of the heat equation

$$(3.13) u(x,\tau) = \sum_{\ell=1}^{\infty} a_{\ell} \sin\left(\frac{\ell\pi x}{L}\right) \exp\left(\frac{-\ell^2 \pi^2 \alpha^2 \tau}{L^2}\right), x \in [0,L], \tau \in [0,T],$$

which can be derived analytically for the initial condition

(3.14)
$$u(x,0) = f(x) = \sum_{\ell=1}^{\infty} a_{\ell} \sin \frac{\ell \pi x}{L}, \quad x \in [0, L],$$

with $a_{\ell} \in \mathbb{C}, \ell \in \mathbb{N}$, using Fourier's approach.

While this solution holds for arbitrary $\tau \geq 0$, we set the final time T=1. Further, we set the length L=1 and the diffusivity constant $\alpha=0.25$. Due to the time-dependence of the differential equation (3.12), the function space $\mathcal U$ is a little more complicated than in the previous examples. We need to ensure spatial regularity, meaning that u should be square-integrable in time and satisfy $u(\tau) \in H^1_0(\Omega)$ for almost every time τ since the term $\partial_{xx}u$ and homogeneous boundary conditions are present. Additionally, we require a notion of time regularity: the weak time derivative of u should exist and take values in the dual space $H^{-1}(\Omega)$. A formal and compact way to express this space uses so-called Bochner spaces (see, e.g., [11, Sec. 5.9.2] or [1]), which we omit here for simplicity. Accordingly, we have $\mathcal F=L_2(\Omega)$ to ensure that the initial state u(x,0) is square-integrable over the spatial domain Ω . Due to the time dependence, the solution operator we are analyzing this time is of the form $\mathcal G:\mathcal F\times[0,T]\to\mathcal U$; cf. Remark 2.2.

We parameterize the function f by truncating the sum (3.14) to n terms. Similar to Section 3.1.1, we restrict the coefficients $a_\ell \in [-1,1]$, for all $\ell=1,\ldots,n$, and transform both the spatial and time variable by $\mathcal{T}x = \frac{1}{2}(x+1)$ and $\mathcal{T}\tau = \frac{1}{2}(\tau+1)$. The differential equation is solved using SciPy's function <code>solve_ivp</code>. In particular, we use the Radau IIA implicit Runge-Kutta method of order five, suitable for stiff differential equations with a desired relative tolerance of 10^{-8} and absolute tolerance of 10^{-10} . We choose the number of coefficients n=9 to end up with an 11-dimensional approximation problem, the sparsity s=1000, and the extension N=64 for our algorithm. Note that using <code>solve_ivp</code> is a very costly approach for the solution of the heat equation, requiring roughly 20 seconds for a single sample of the solution. Therefore, the execution of our full algorithm takes around 32 hours.

Figure 3.10 displays the relative approximation error $\operatorname{err}(a)$ computed for 10000 randomly drawn coefficients a. The error is computed similarly to (3.2) for 100 equidistant nodes in space and time each and using the exact solution (3.13) as comparison. The average error size is less than 10^{-4} for this example. Note that the function $\operatorname{solve_ivp}$ itself reaches an accuracy of around 10^{-6} with the given parameters, which can be seen as the noise in the data samples that we give to our dimension-incremental method here.

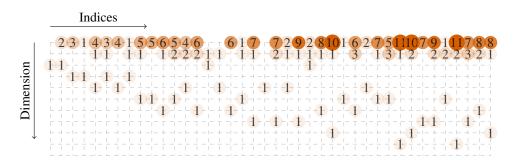

FIG. 3.11. An abstract visualization of the first 40 indices \mathbf{k} detected for the heat equation example. The indices \mathbf{k} are ordered by the absolute values of their corresponding approximated coefficients $\hat{\mathbf{u}}_{\mathbf{k}}$ in descending order from left to right. The rows identify the 11 dimensions corresponding to the spatial variable x, the time variable τ , and the n=9 coefficients \mathbf{a} used. Zeros are neglected to preserve clarity.

This time the detected index set I shows several interesting features. As can be seen for the first 40 indices in Figure 3.11, the dimensions corresponding to the coefficients a_ℓ contain exactly one non-zero entry for each index, which happens to be 1. This remains true for all the detected indices up to some artifacts again. As in previous examples, this is due to the fact that the coefficients a_ℓ appear only linearly and separated from each other in the sum in (3.13). Our algorithm once again captures this behavior even for this more complicated example. The size of the entries in the first dimension, i.e., the dimension corresponding to the spatial variable x, seems to grow rapidly and much faster than in the second dimension corresponding to the time variable τ . However, the largest entries in the first dimension is 24 while the largest one in the second dimension is 22. For increased sparsity s, the size of the entries in the first dimension stays the same while larger entries in the second dimension are added. This again confirms that the time-dependent exponential term in (3.13) is the main difficulty in this approximation problem.

3.6. Burgers' equation. Our final example will be the nonlinear Burgers' equation in one dimension with homogeneous boundary conditions, i.e.,

$$\begin{split} \partial_{\tau} u + u \partial_{x} u &= \nu \partial_{xx} u, & x \in (0, L), \ \tau \in (0, T), \\ u(x, 0) &= f(x), & x \in (0, L), \\ u(0, \tau) &= u(L, \tau) = 0, & \tau \in (0, T). \end{split}$$

We will use the viscosity $\nu=0.05$ here. As in the previous example, we set the final time T=1 and the length L=1, i.e., $\Omega=(0,1)$. However, this time we are only interested in the solution u at the final time T=1, i.e., u(x,1). This again complicates the notion of our solution space $\mathcal U$ a little, which is why we omit it here. The idea, however, is similar to the one described for the heat equation, adjusted accordingly to the neglection of the time variable τ .

We use the approximation via the sine expansion

(3.15)
$$f(x) \approx \sum_{\ell=1}^{n} a_{\ell} \sin(\ell \pi x), \quad x \in [0, 1],$$

for the initial condition f as our parameterization. This approach is similar to the one in Section 3.5. Analogously, we restrict $a \in [-1,1]^n$, transform $\mathcal{T}x = \frac{1}{2}(x+1)$, and set the number of coefficients n=9, such that we end up with a 10-dimensional approximation problem. Further, we use the sparsity s=500 and the extension N=32 here. We use the function $solve_ivp$ with the Radau method again, this time with the relative tolerance

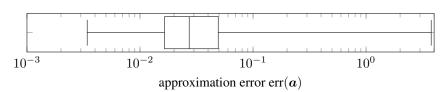

FIG. 3.12. The relative approximation error err(a) for 10000 randomly drawn a for the Burgers' equation example. The box-and-whisker plots show the median, the first and the second quartile, as well as the maximal and minimal error observed.

 10^{-6} and the absolute tolerance 10^{-8} . The solver itself then needs about 6 seconds for each solution. However, the more difficult structure of the index set that we are detecting due to the nonlinearity of our problem leaves our full method with a runtime of roughly 114 hours.

In Figure 3.12 we directly observe that the relative approximation error $\operatorname{err}(a)$ is way larger than for the heat equation in Section 3.5. The nonlinearity of the Burgers' equation increases the difficulty of this approximation problem significantly, even when neglecting the time variable τ here. However, the error is of the order of 10^{-2} most of the times, which is still reasonable given this difficulty and the smaller sparsity s=500 used here. Note that approximation errors $\operatorname{err}(a)$ exceeding 10^{-1} occur only rarely and would be classified as outliers under the common convention of using 1.5 times the interquartile range.

Next, we are interested in an explicit solution to the Burgers' equation. If we use the initial condition

(3.16)
$$f(x) = 2\pi\nu \frac{\sin(\pi x)}{\alpha + \cos(\pi x)}, \qquad x \in [0, L],$$

then the solution u is given as

(3.17)
$$u(x,\tau) = 2\pi\nu \frac{\sin(\pi x) \exp(-\pi^2 \nu \tau)}{\alpha + \cos(\pi x) \exp(-\pi^2 \nu \tau)}, \qquad x \in [0,L], \tau \in [0,T].$$

Further details and other explicit solutions to the Burgers' equation can be found in [4]. We set $\alpha=2$ here and approximate (3.16) by an (n=9)-term sine expansion of the form (3.15), which yields a relative error of less than 10^{-5} . Note that the corresponding coefficients a_{ℓ} have absolute values of less than 0.2, matching our initial restriction $a_{\ell} \in [-1, 1]$.

Although we are starting with just an approximation of the true initial condition (3.16), we end up with a reasonable solution as shown in Figure 3.13. We notice the smooth oscillations of our approximation around the true solution, which could of course be further reduced by increasing the sparsity s and the extension N.

Finally, Figure 3.14 displays some of the detected indices for this example. We observe a similar behavior in the first dimension corresponding to the spatial dimension x as in previous examples. However, for the remaining dimensions corresponding to the coefficients a_{ℓ} , two main differences can be seen: First, the entries in these dimension are not only 0 and 1, i.e., the solution does not depend only linearly on the coefficients a_{ℓ} . Second, there are several noticeable interactions between these dimensions (and the spatial dimension x). While we saw both effects already in the example in Section 3.1.2, they are much more prominent here, i.e., occurring way earlier (in the first 10 indices) and stronger (up to six non-zero entries).

4. Conclusion. We have presented an adaptive approach that uses the dimension-incremental algorithm from [24] in combination with classical differential equation solvers like the FEM to approximate solution operators of differential equations. We transform the problem of operator learning for differential equations by parameterizing, e.g., the source function f,

APPROACH TO DISCRETE OPERATOR LEARNING VIA SPARSE APPROXIMATION

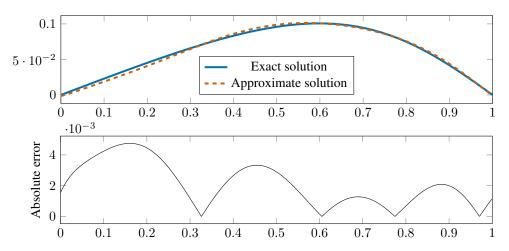

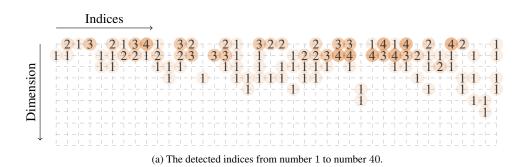

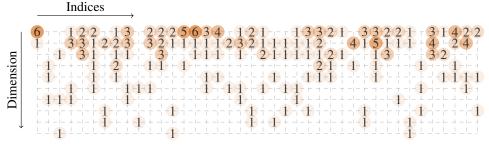

FIG. 3.13. Comparison between the exact solution (3.17) and the approximate solution at $\tau = 1$ and the corresponding (absolute) pointwise approximation error.

(b) The detected indices from number 201 to number 240.

FIG. 3.14. Abstract visualizations of 40 detected indices k (from left to right) for Example 3.6. The indices k are sorted in descending order according to the size of the corresponding approximated coefficient \hat{u}_k . The rows identify the 10 dimensions corresponding to the variables x and a_1, \ldots, a_9 from top to bottom in this order. Zeros are neglected to preserve clarity.

which leads to a high-dimensional approximation problem for a function with an unknown structure. Algorithm 1 detects a reasonable index set I by using samples of the solution u computed by the differential equation solver mentioned above. This index set I not only allows for a good approximation of the respective solution u for any source function f suitable to this parameterization but also gives us important information about the structure of the solution and

its dependence on the spatial variable x, the discretization parameters of the source function f, and possible other variables and parameters such as the time t. Such information can then be used to manually generalize the index set I to even higher dimensions that arise when refining the resolution of the source function f.

We have studied the behavior of our proposed methods for several examples. These numerical tests yield reasonable approximations to the solutions of the PDEs. Especially for the easier examples, the structure of the obtained index sets I matches our general expectations and (if available) the structure of the underlying analytical solution. Our brief test of generalization of the index set I to even higher dimensions for the one-dimensional Poisson equation also shows promising results. The more advanced examples demonstrate the applicability of our approach to more difficult settings and problems. Our numerical tests are available at https://github.com/fabiantaubert/nabopb together with the dimension-incremental algorithm itself.

Overall, the presented algorithm performs satisfactorily and provides useful details about the structure of the solutions to the differential equations. Thus, while the field of operator learning is strongly dominated by machine learning algorithms such as PINNs, more classical approaches such as our proposed method can open new perspectives, especially to overcome still existing drawbacks of neural networks like the lack of interpretability.
